ABSTRACT

The emission line objects are very important objects in astronomy because reflects different class of objects that evolved physical mechanics that given counts of stellar formation process, presences the gas, shocks, star-burst in galaxies, the finals stage of stars among others process. For this reason we have created a list of H α emitters selected from the S-PLUS data, which is mapping the southern hemisphere at relatively high latitudes. We implemented the (r - J0660) versus (r - i) color-color diagram for that task. We found 9,200 objects that exhibit um excess in emission in the J0660 which we have traduced as the presence of the H α emission line. In addition we have found that by combining the colors: (r - i) and (g - z) with unsupervised (clustering) machine learning it is possible separate the blue sources from red ones, then we ave divided our list of emitters in two sub-groups: one with intense blue continuum and another with intense red one. We compare hierarchical-clustering algorithm with the HDBSCAN. By adopting a “soft” clustering approach, we can assign each emission object a probability of belonging to a given cluster (blue or red group), allowing for more flexibility in the classification of objects according to these colours those objects with a low probability of belonging to any cluster.

Key words: surveys – stars: emission-line, Be – novae, cataclysmic variables – galaxies: dwarf – quasars: emission lines

1 INTRODUCTION

The existence of an ionizing radiation field can lead to Balmer hydrogen emission lines. From the presence of the H Balmer lines in the optical spectra of some sources it is well known the possible presence of ionized gas. Many important astronomical objects involve the physics of photo-ionized gases and the interpretation of the emission-line spectra. Emission line objects as the H II regions allow us to study the star formation history of the far reaches of our Galaxy and of distant galaxies. Planetary nebulae let us to see the remaining envelope of dying stars. Star-burst galaxies and QSOs are one the most luminous objects and hence the most distant that can be observed. Their spectra can reveal details about of the first generation of star and the formation of heavy elements in the young universe. On the other hand, emission lines can also infer the presence or lack the accretion discs (Schwope et al. 2000; Ratti et al. 2012), the properties of single or double picked line can allow us to infer geometrical characteristics (Horne & Marsh 1986), the nature of donor stars in binary system (Steeghs & Casares 2002; van Spaandonk et al. 2010; Casares 2015) and the compact objects as black holes (Casares 2016).

Emission lines are also associated with stars in very early-type and/or very late evolutionary stage which are short phase. As already mentioned are also associated with binaries that experiencing mass transfer. These group of emission line stars includes young stellar (YSOs) and Herbig-Haro (HH) objects, post-asymptotic and

some asymptotic giant branch (AGB), some red giant stars (RGB), Wolf-Rayet (WR) stars, supernova remnants, classical Be stars, active late-type dwarfs, interacting binary system like symbiotic stars (SySt) and cataclysmic variables (CV). Most of these class of object are in-homogeneous and some contains many few identified members, for instance at the moment around 323 symbiotic system have been identified from which 257 belong to the Galaxy and ~66 are extra-galactic objects (Akras et al. 019a). The same occurs with PNe from witch around 3500 of them are been cataloged (Parker et al. 2016), this current number of PNe represents only about 15-30% of the estimated total of Galactic PNe (Frew, 2008; Jacoby et al., 2010) showing that a small fraction of the PNe have been cataloged. Many galaxies, in addition to harbor Planetary nebulae and H II regions, show characteristic nebular in their spectra. In most of these objects, the gas is photoionized by hot stars in the nucleus, which is thus much like giant H II region, or perhaps many H II regions. The galactic nucleus with very strongest emission lines of this type are often called blue compact galaxies, extragalactic H II regions, star forming or starburst galaxies (Osterbrock & Ferland 2006). There are also spiral galaxies that present emission lines.

In the past H surveys with modest spatial resolutions have been used to identified extended nebular emission to study supernova remnants, galaxy groups and star forming regions (Davies, Elliott Meaburn 1976). More recently, higher resolution surveys such as the INT Photometric H α survey (IPHAS; Drew et al. 2005; Barrentsen et al. 2014) have focused in the study of compact emission line sources on the Galactic plane, typically with objects in different stage of stellar evolution. The Anglo-Australian Observatory UKS

chmidt Telescope Supercosmos H α Survey (Parker et al. 2005) is another H α survey of the Southern Galactic Plane and Magellanic Cloud which has covered to $b \sim 10\text{--}13^\circ$ (verificar esto). Currently ongoing is the VST Photometric H α Survey of the Southern Galactic Plane and Bulge (VPHAS+; Drew et al. 2014) that will cover the Galactic bulge and plane in five filters.

Like VPHAS+, others ongoing surveys that are used to study the population of emission line objects are the The Javalambre Photometric Local Universe Survey (J-PLUS¹, Cenarro et al. 2018) and the Southern-Photometric Local Universe Survey (S-PLUS², Mendes de Oliveira et al. 2019) are providing observations of the Galactic halo covering both northern and southern celestial hemispheres in a systematic way with twin telescopes using the same set of multi-band filters. In addition to the H α filter, which is already vastly applied to systematically searching for H α emitters the telescopes offer 11 more filters. And more ambitious yet the JPAS survey that will the same area of J-PLUS in 56 narrow-band filters.

Traditionally, color-color diagrams based in H α filter are been used to identify H α emitters. The analysis the color-color diagram ($r - H\alpha$) versus ($r - i$) has resulted on the discovered of new emission line objects, for instance Witham et al. (2006, 2007) used the ($r - H\alpha$) versus ($r - i$) colour-colour diagram to find for new CV. On the other hand, Vink et al. (2008) reported the discovery of YSOs by using this same colour criteria. In this sense using this methodology a variety of classes of objects are been identified, which include symbiotic stars (Corradi et al. 2008; Corradi & Giannanco 2010; Corradi et al. 2011), early type emission line stars (Drew et al. 2008) and planetary nebulae (Viironen et al. 2009; Sabin et al. 2010). Recently, by using this same color diagram were also identified compact PN candidates in VPHAS+ catalog (Akras et al. 2019). And the same diagram in conjunction with new ones shows to be very efficient to find for PN candidates (Gutiérrez-Soto et al. 2020). In general terms, Witham et al. (2006) presented a methodology and first results in looking for emission line sources in narrow-band surveys.

In this era of big data on astronomy, machine learning techniques are becoming in important statistical tools for the analysis and find meaning from massive data sets. Particularly, unsupervised machine approaches have showed a promised in various applications, especially in automatic classification task. Including object classification and selection, using galaxies with active galactic nuclei as example (Geach 2012), morphological analysis of galaxies (Martin et al. 2020), classification of variable stars, relying only on the similarity among light curves. (Valenzuela & Pichara 2018). Using unsupervised machine learning can be very advantageous because they do not require a labeled data training sets. Unlike of supervised methods like Random Forest algorithm. Instead, unsupervised techniques are generally based in the data itself to identify patrons, e. g. cluster of similar objects, in some pre-defined feature space where the data are defined.

In this work, we used S-PLUS observations of the southern hemisphere to search for objects with an excess of H α using automatic methods based on the ($r - H\alpha$) versus ($r - i$) color-color diagram we also used color criteria based in ($g - r$) and ($z - g$) in conjunction to unsupervised machine learning techniques to split the final list in those with blue and red continuum. The paper is organized as follows...

Figure 1. Transmission curves of the S-PLUS filters set. The narrow-band filter J0660 detects the H α emission line. Over-plotted are different classes of emission line objects, from upper to down PN, SySt ...

2 OBSERVATIONS: THE S-PLUS PROJECT

We are implemented data from S-PLUS DR3 (ref) to carried out our study. S-PLUS is 12-band optical photometric survey, which are formed by seven narrow-band ($J0378$, $J0395$, $J0410$, $J0430$, $J0515$, $J0660$ and $J0861$) and five broad-band like SDSS filters (u, g, r, i and z , Fukugita et al. 1996). The narrow-band set include the filter J0660 which detect the H α emission line. For more detailed about the configuration of S-PLUS filter set see Figure 1 shows the Javalambre filter system (Marín-Franch et al. 2012) overlapping are the optical spectra of several class emission line objects on which it is possible to see that the H α line falls into the J0660 filter, except for the QSOs.

The actual data release contains about 60 millions of objects covering a total area of $\sim 8000 \text{ deg}^2$, at high Galactic latitudes ($> 30 \text{ deg}$) using a dedicated 0.83m robotic telescope, the T80-South (T80S), located at Cerro Tololo, Chile. S-PLUS will cover an additional 1300 deg^2 of the Galactic plane and bulge to enable Galactic studies. In this work, we focus on the aspects that are of particular interest to the second data release of the S-PLUS main survey. Additional information about S-PLUS can be found in Mendes de Oliveira et al. (2019).

3 METHODOLOGY

We first constructed a sub-sample from all S-PLUS DR3 from which we applied an iterative and automatic technique to select objects with an excess of H α emission line. Once the objects were selected we also make a separation of them into two groups those with red and blue continuum by using optical colors in conjunction with unsupervised machine learning statistical tools. These procedures are described below:

3.1 Initial selection sample

The first step in our selection procedure consist in the following criteria to guarantee the quality of the observations of the objects:

- (i) The sources must have detection in the filters: r, i and $J0660$. To assure that we select object must have error minor or equal to 0.2 in each of three filters.
- (ii) Must have an r magnitude until $r = 21$.

3.2 Finding the main stellar locus and selecting the H α emitters

Once the initial cut were made, we proceed to select the objects with an excess of H α which is represent with a relatively high value of the

¹ <https://www.j-plus.es>

² <http://www.splus.iag.usp.br>

filter $J0660$ in comparison with r-band filter. For that we first divided our sub-sample in for magnitude bins using the r -band magnitudes. The bins have the follow distribution:

- 1 bin- objects with magnitude in the r -band $r < 16$
- 2 bin- objects with magnitude in the r -band $16 \leq r < 18$
- 3 bin- objects with magnitude in the r -band $18 \leq r < 20$
- 4 bin- objects with magnitude in the r -band $20 \leq r < 21$

To select the emission lines we used the same method created and implemented by [Witham et al. \(2008\)](#) its possible to do that because the S-PLUS has similar filters that the IPHAS project, which are r , $J0660$ and i . This technique was used by [Scaringi et al. \(2013\)](#) to identify blue objects with excess of $H\alpha$ and after that [Wevers et al. \(2017\)](#) also applied this methodology to create catalogue of candidate $H\alpha$ emission showing an high effectiveness. In this order of ideas we attempted this methodology in S-PLUS.

We first generated the ($r - J0660$) versus ($r - i$) color- color diagram for each magnitude bins. We then carried a out an initial straight line fit to all objects in each magnitude bin. This initial fit is an attempt to find the loci of main-sequence and giant stars. We implemented a iterative σ -clipping tecnicue to find the best-fitting of the main stellar locus. In this order of ideas, we made four interactive σ -clipped. Once we have found the apropiate fitting for each maginitude bin, we identified those objects significantly above of this final fit as likely sources with a excesses of $H\alpha$. Objects with a contribution significative of $H\alpha$ meet the condition:

$$(r - J0660)_{\text{obs}} - (r - J0660)_{\text{fit}} \geq C \times \sqrt{\sigma_s^2 - \sigma_{\text{phot}}^2} \quad (1)$$

where σ_s is the root mean squared value of the residuals around the fit and σ_{phot} is the error on the observed ($r - J0660$) colour index. C is a constant which has the value 4 following [Wevers et al. \(2017\)](#). The fits are carried out with the aid of the python library `astropy.modeling`³.

Figure 2 illustrates the procedure used to slected the $H\alpha$ emitters in S-PLUS DR3 for each magnitude bin. The continuos black lines represent the initial fit and the dashed lines indicate the 4- σ clipping fit lines. The dotted lines are the cut selection criteria for the $H\alpha$ emitters – the 4- above of the final fit-. Note that theses cut lines are only an approximations because to trace these lines it is only considered the residual around the fit. The actual selection criteria used here also include the photometric uncertainties in $r - J0660$ for each individual data source as shows on the Equation 1.

After the algorithm was applied to all data, we visually inspectioned the resulting list by seeing the S-spectra and corresponding colored image. The figure 3 shows an example of how looks like a S-spectra⁴ of sources in magnitude unities selected with methods explained above. This object clearly exhibits strong $H\alpha$ emitter.

Once, we felt confident of our sample of $H\alpha$ emission lines sources, we proceeded to classify the objects into two big groups; one group containing those objects with a strong blue continuum and another with an intense emission of the continuum on the blue part of the spectrum.

³ <https://docs.astropy.org/en/stable/modeling/index.html>

⁴ S-spectra signify the S-PLUS emission in flux or magnitude unities of an object in all twelve bands.

3.3 Unsupervised machine learning/clustering techniques

In this work we are using unsupervised machine learning approaches to divided our sample in two groups: one represent the blue sources and the another one are the red sources. The blue are those that have strong emission of the continuum on the part blue of the spectrum and the another with strong emission continuum of the red one. For that task, was performed two clustering techniques; hierarchical clustering and Hierarchical density-based cluster selection

3.3.1 Hierarchical clustering

Hierarchical clustering belong to the family of clustering algorithms on which are constructed cluster by merging clusters and splitting them successively. It is an unsupervised algorithm that yields a dendrogram representing the nested grouping of patterns and similarity levels at which groupings change ([Jain et al. 1999](#)). There is two type of hierarchical clustering: one is the *agglomerative hierarchical clustering* which is “bottom-up” approach. Hierarchical agglomerative clustering (HAC) consists of building a binary merge tree, starting from the data elements stored at the leaves (interpreted as individual cluster) and proceed by merging two by two the “closest” sub-sets (stored at nodes) until it reaches the root of the tree that contains all the elements of the data set. Agglomerative term used to define it since the individual data point are successively agglomerated into higher-level. In each iteration, two cluster are selected that are considered as close as possible. These cluster are merged and replaced with a newly created merged cluster. Thus, each merging step reduces the number of cluster by “1”. Therefore, the method needs to be designated for measuring proximity between cluster containing multiple data points, so that they may be merged ([Aggarwal 2015](#); [Mann & Kaur 2013](#)). We could describe how to work the algorithm in three simple steps:

- (i) Initially all the data points that are cluster i.e. leaf.
- (ii) It looping merges the nodes (cluster) that have the maximum similarity between them.
- (iii) At the end of the process all the nodes belong to unique cluster. This is known as the root of the tree structure.

The other type is the *agglomerative hierarchical clustering*. This is a “top-down” approach. The data start in one cluster, and splits are performed recursively as one moves down the hierarchy. It is the inverse procedure of HAC.

In this work we have used the HAC technique for classify our sample. In simple words HCA can be interpreted as an algorithm that groups similar objects into groups called clusters or nodes. The endpoint is a set of clusters, where each cluster is distinct from each other cluster, and the objects within each cluster are broadly similar to each other.

Choosing the number of cluster. Firstly, the Hierarchical cluster output dendrogram (tree) can be implemented to obtain the desired clustering. Secondly, the dendrogram schema allows a convenient way to establish the entity relationship between at all levels of granularity. In conclusion, a dendrogram is a visualization in form of a tree showing the order and distances of merges during the hierarchical clustering.

- On the x axis you see labels. If you do not specify anything else they are the indices of your samples in X .
- On the y axis you see the distances (of the “ward” method in our case).

Dendrogram Truncation

Figure 2. An illustration of the selection criteria used to identify strong emission-line objects via colour-colour plots. The data shown here are all from the S-PLUS DR3. The data are split up into four magnitude bins, as shown in the four panels. Objects with H α excess should be located near the top of the colour-colour diagrams. The thin red lines illustrate the original linear fit to all the data (grey points). The dashed lines represent the final fits to the stellar locus of points which were obtained by applying an iterative σ -clipping technique to the initial fit. The actual cuts used to select H α emitters are shown by the dotted lines. Objects selected as H α emitters must be located above. Note that the cut lines (selection criteria) shown here are only approximate, as the actual selection criterion also considers the errors on each source. This means that an object could be in the bottom right-hand panel is not selected despite clearly lying above the cut line (EXPLICAR ESTA ÚLTIMA FRASE MEJOR).

As you might have noticed, the above is pretty big for many samples already and you probably have way more in real scenarios, so let me spend a few seconds on highlighting some other features of the dendrogram() function:

Starting from each label at the bottom, you can see a vertical line up to a horizontal line. The height of that horizontal line tells you about the distance at which this label was merged into another label or cluster. You can find that other cluster by following the other vertical line down again. If you don't encounter another horizontal line, it was just merged with the other label you reach, otherwise it was merged into another cluster that was formed earlier.

Hierarchical clustering can be performed with either a distance matrix or raw data. When raw data is provided, the software will automatically compute a distance matrix in the background. The distance matrix below shows the distance between six objects.

Hierarchical clustering starts by treating each observation as a separate cluster. Then, it repeatedly executes the following two steps: (1) identify the two clusters that are closest together, and (2) merge the two most similar clusters. This iterative process continues until all the clusters are merged together. This is illustrated in the diagrams below.

Hierarchical clustering 2

Figure 3. S-spectra of a random object observed by S-PLUS. Squares represent the SDSS-like broad-band filters. From left to right they are u, g, r, i and z . Circle symbols are the narrow-band filters, which from left to right represent J0378, J0395, J0410, J0515, J0660 and J0861.

3.3.2 Hierarchical density-based cluster selection

Hierarchical density-based cluster selection (HDBSCAN, Campello et al. 2013) is another unsupervised machine learning algorithm that hinges on clustering. It is based on a slightly modified version of Density-based Spatial Clustering of Applications with Noise (DBSCAN; Ester et al. 1996) which declare points as noise. It is a algorithm that assumes clusters are characterized by “islands” of high density in the sea of the parameter space, such that clusters are regarded as data partitions that have a higher density than their surroundings (Ntwaetsile & Geach 2021). HDBSCAN takes forward the DBSCAN concept by introducing a hierarchy to the clustering, with “persistent” clusters finally extracted from the hierarchical tree. The main advantage of HDBSCAN in comparison with the predecessor consists in the possibility in finding clusters of variables densities and different shape.

HDBSCAN is a recent algorithm developed by some of the same people who write the original DBSCAN paper. Their goal was to allow varying density clusters. The algorithm starts off much the same as DBSCAN: we transform the space according to density, exactly as DBSCAN does, and perform single linkage clustering on the transformed space. Instead of taking an epsilon value as a cut level for the dendrogram however, a different approach is taken: the dendrogram is condensed by viewing splits that result in a small number of points splitting off as points ‘falling out of a cluster’. This results in a smaller tree with fewer clusters that ‘lose points’. That tree can then be used to select the most stable or persistent clusters. This process allows the tree to be cut at varying height, picking our varying density clusters based on cluster stability. The immediate advantage of this is that we can ave varying density clusters; the second benefit is that we have eliminated the epsilon parameter as we no longer need it to choose a cut of the dendrogram. Instead we have a new parameter `min_cluster_size` which is used to determine whether points are “falling out of a cluster” or splitting to form two new clusters. This trades an unintuitive parameter for one that is not so hard to choose for EDA (what is the minimum size cluster I am willing to care about?).

Hierarchical Density-Based Spatial Clustering of Applications with Noise (Campello, Moulavi, and Sander 2013), (Campello et al. 2015). Performs DBSCAN overvarying epsilon values and integrates the result to find a clustering that gives the best stability over epsilon. This allows HDBSCAN to find clusters of varying densities (unlike DBSCAN), and be more robust to parameter selection. The library also includes support for Robust Single Linkage clustering (Chaudhuri et

al. 2014), (Chaudhuri and Dasgupta2010), GLOSH outlier detection (Campello et al. 2015), and tools for visualizing and exploring cluster structures. Finally support for prediction and soft clustering is also available.

There have been few times that it has been used HDBSCAN in astronomy. Recently, Ntwaetsile & Geach (2021) used it to group radio sources into a sequence of morphological classes, illustrating a simple methodology to classify and label new, unseen galaxies in large samples.

4 RESULTS

4.1 Simbad

We made cross-match between our sample and Simbad. We found 1000 matches that include a big variety of emission line objects:

4.1.1 Nebulae

As was mentioned, objects with nebulosity include several type of objects like H II region and planetary nebulae. The H II regions are objects with gas that being ionized by amounts of UV light come from massive stars (OB type) on which are formed the emission lines. In theses clouds of ionized nebulae new stars are formed. Unlike H II regions, planetary nebulae represent the final stages of low- and intermediate-mass stars where the gas previously ejected in the phase of AGB is ionized by their central star.

In our list of $\text{H}\alpha$ emission line a PN () appears cataloged in SIMBAD. This objects is a very interesting because is one of the twelves PNe that belong to the Galactic halo. These PNe are low metallizite and present large velocities that can give cont of the origin and nucleis in the early universe.

30 HII regions listed on the SIMBAD database are in our sample of $\text{H}\alpha$ emitters

4.2 SDSS

4.3 Lamost

5 CONCLUSIONS

We have found a important sample of emission line objects.

APPENDIX A: CONDENSED TREES

The question now is what does the cluster hierarchy look like - which clusters are near each other, or could perhaps be merged,

and which are far apart. We can access the basic hierarchy via the `condensed_tree_` attribute of the clusterer object. It is possible to see that HDBSCAN has found two cluster that in agreement with previous results are the blue and red sources.

Figure 12. Spectra of the known objects select with our algorithm

**Figure 13.** Spectra of the known objects select with our algorithm

Figure 14. Spectra of the Lamost

**Figure 15.** Spectra of the SDSS

Figure A1. Branches were selected by the HDBSCAN* algorithm.

APPENDIX B: SIMBAD OBJECTS

Table B1: Simbad sources.
